

Guis and event driven CRT

1. An event-driven application responds to actions like button clicks. A console-based application uses text input and output and usually follows a set sequence.
2. When an event occurs, a listener detects it and calls an event handler, such as `actionPerformed()`, to execute the code.
3. Components belong in the frame's content pane. Calling `frame.add(component)` automatically adds them to that pane.
4. A label does not normally respond to action events. It displays text or images.
5. The event-dispatching thread processes GUI events and updates components in order, helping prevent conflicting changes.
6. A label displays information. A button lets the user click it to trigger an action.
8. Three ways are using layout managers, adding borders for spacing, and setting component alignment.
13. The text must be converted into a numeric type, such as `int` or `double`, before calculations.
14. `num1` equals `8.0`, because the code converts "5" to a number and adds it to `3.0`.
15. A combo box is better because the user can select one of the six names without typing or making spelling mistakes.
